Severity of adverse reactions in children

May 31, 2020

1 Severity of adverse reactions in pediatric patients

1.1 Data collection and cleaning

We will first collect the data. We will initially collect only data for 'children' i.e. patient age group '3' as reported in the database. This does not include neonates, infants or adolescents.

Given the total number of children in the database (35,000), we will initially restrict our analyses to the first 5,000. The sample can be expanded or reduced by changing n_reports.

```
[1]: # import standard modules necessary for data processing and visualisation
     # set style for plotting
     import pandas as pd
     import seaborn as sns
     import matplotlib.pyplot as plt
     import numpy as np
     from matplotlib.colors import LogNorm
     import scipy.stats as st
     plt.style.use('seaborn')
     plt.rcParams['figure.figsize'] = (10.0, 6.0)
     # import my modules
     import collect_data
     import clean_data
     import process data
     # define the base of the URL used to access the database
     # search terms will be appended to this to obtain specific recordsets
     url_base = "https://api.fda.gov/drug/event.json?search=receivedate:
      \hookrightarrow [20030101+T0+20200528]"
```

1.1.1 Collecting the pediatric dataset

```
[2]: n_reports = 5000

# collect pediatric data from database and flatten
raw_pediatric = collect_data.collect_pediatric_data(n_reports)
```

```
raw_pediatric.reset_index(drop=True, inplace=True)
flat_pediatric = collect_data.flatten_dataframe(raw_pediatric)
```

HBox(children=(FloatProgress(value=0.0, description='Progress', max=50.0, style=ProgressStyle(

```
[3]: flat_pediatric.head(5)

[5 rows x 87 columns]

We can see that we have a flattened dataframe, with no nested dictionaries or lists (in any desired columns). However, it is also clear that there are numerous missing values and a large number of columns (87). We must reduce this featureset and clean the data before analysis.

1.1.2 Cleaning the data

We clean the data to remove unnecessary/undesired columns, impute missing values (where appropriate), remove columns with a high fraction of missing values, format types appropriately, and filter any outliers.

```
[4]: # remove unnecessary columns
     clean_pediatric = clean_data.drop_unnecessary_columns(flat_pediatric)
     # replace missing values in seriousness outcome columns with O
     # assume that no entry means this outcome did not take place
     clean pediatric = clean data.fill seriousness nan(clean pediatric)
     # remove any columns which have more than 40% msising values
     clean_pediatric = clean_data.remove_nan_columns(clean_pediatric, 40)
     # fix data types and formatting
     clean_pediatric = clean_data.fix_data_types(clean_pediatric)
     clean_pediatric = clean_data.reformat_onsetage(clean_pediatric)
     # remove outliers in patient age category
     clean_pediatric = clean_data.remove_outliers(clean_pediatric)
     # remap seriousness from {1, 2} to {1, 0}
     clean_pediatric.serious = clean_pediatric.serious.map({2:0, 1:1}) #mapu
     ⇔serious to boolean
     pediatric_data = clean_pediatric.reset_index()
```

Examine the cleaned and reduced dataset by eye to look for anomalies and problems.

```
[5]: # preview data
pediatric_data.head(10)
```

```

Not all of this data is meaningful but we can still see some useful properties of the data from these statistics.

Basic checks of the boolean and categorical data have maxima and minima as expected. The means of the boolean data give an indication of the skew, e.g. 54% of the reports are 'serious', defined as an adverse event resulting in death, a life threatening condition, hospitalization, disability, congenital anomaly, or other serious condition. We can also quickly see that the data are skewed towards male patients and that a serious outcome of 'other' is reported for almost 50% of the dataset.

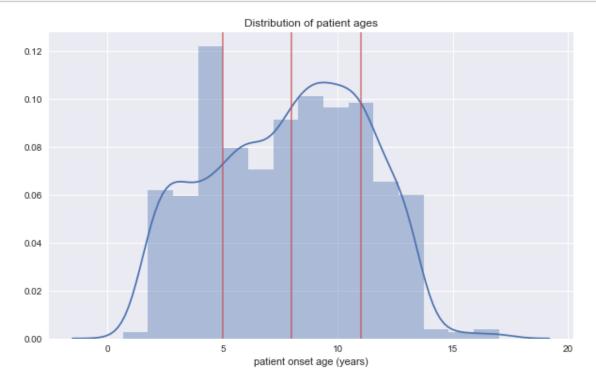

The only continuous numerical data in this dataset is the age of the patient at the onset of the adverse response. The oldest patient in our sample is 17 (we removed any outliers above this threshold) whilst the youngest is 0.6 years. The 'children' category on which the data was selected encompasses a wide range of (pediatric) ages. More detailed future analysis should consider selecting data across all pediatric categories rather than just 'child' since it seems the categories are subject to some interpretation.

Within this data, the standard deviation of patient age is 3.3 years with a mean of 7.8 years. We plot the distribution below and mark the quartiles in red.

```
[7]: # plot distribtuion of patient ages
data_age = pediatric_data['patient.patientonsetageyear']
ax = sns.distplot(data_age, bins=15, kde=True);
ax.set_xlabel('patient onset age (years)');
ax.set_title('Distribution of patient ages');

# plot the quartiles
for q in [0.25,0.5,0.75]:
```

1.2.2 Exploring types of adverse response outcomes

Similar to our analysis for the full database (presented in the Exploring_OpenFDA_Adverse_Reactions notebook), we can now analyse the cleaned pediatric dataset. We are primarily interested in the severity of the adverse response and so we start by exploring this feature.

We begin by considering the relative proportions of seriousness outcomes in the data.

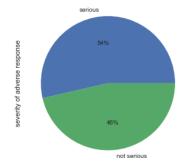

```
labels = [item.replace('seriousness','') for item in seriousness_col_names]

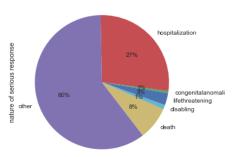

df_serious = pediatric_data[seriousness_col_names]

df_serious.sum().plot.pie(ax=ax2, autopct='%1.0f%%', labels=labels,__

startangle=-20)

ax2.set_ylabel('nature of serious response');
```

We can see that the fraction of reported serious adverse responses is similar to the entire population calculated in our population study (54% compared to 59%). Of those where the nature of the serious reponse was reported, the majority (60%) reported a response that did not result in death, disability, congenital anomali, a threat to life or hospitalisation.

Two different but comparable metrics exist within the database that give an indication of severity. We can gain some understanding of the accuracy of the data by comparing these metrics. We know whether the outcome was classified as 'serious' or 'not serious'. We also have the nature of the outcome as falling into one of these categories:

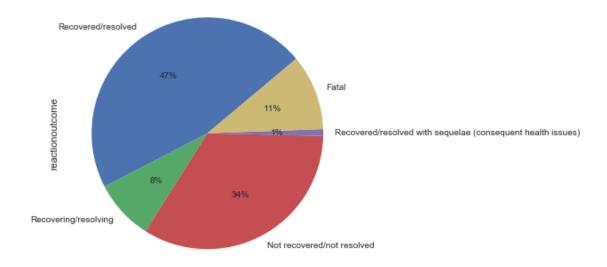

- 1 = Recovered/resolved
- 2 = Recovering/resolving
- 3 = Not recovered/not resolved
- 4 = Recovered/resolved with sequelae (consequent health issues)
- 5 = Fatal
- 6 = Unknown

We can examine the relative frequencies of these outcomes in our data (ignoring any blanks or unknowns).

```
6 : 'Unknown'
}

ax1 = outcome_df[outcome_df.index != 6].plot.pie(autopct='%1.0f%%',

→labels=labels_dict.values(), startangle=40);
```

Some categories can be compared directly. For example the number of reports listing the outcome as 'death' is 11% by this metric compared to 8% by the feature 'seriousnessdeath'. When combined with the relative sparsity of entries in the 'seriousness' fields, we might infer that this metric may be more reliable.

It is noteworthy that many reports indicate multiple serious outcomes, for example hospitalization and death are not mutually exclusive.

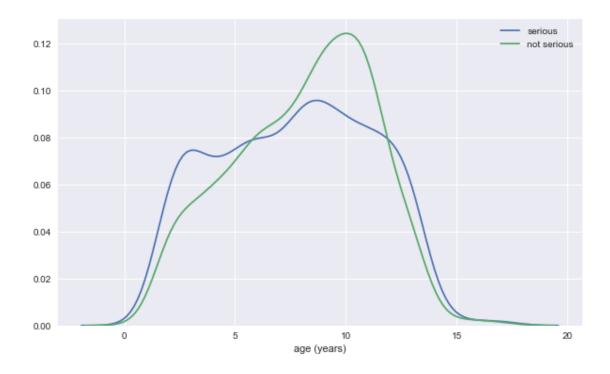

1.2.3 Exploring the impact of age on adverse response outcomes

It seems that reports of serious adverse effects are more likely to be seen in slightly younger patients. We consider their relative distributions and compare them at a 95% significance level using a z-test.

z = 0.0781 critical value = 1.64 Do not reject null hypothesis. Insufficiest evidence for dependence.

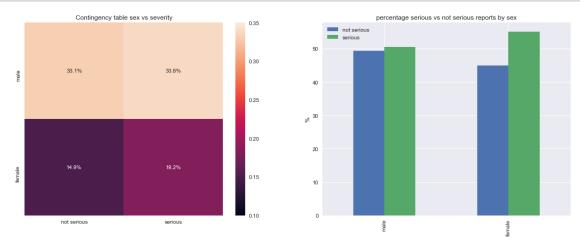

Whilst the 'not serious' responses are more skewed to older children, there is not enough evidence here to reject the null hypothesis that there is no correlation between age and severity of adverse reports.

1.2.4 Exploring the impact of sex on adverse response outcomes

We can also consider the correlation with sex using a contingency table.

```
ax1.set_title('Contingency table sex vs severity')

# plot bar chart showing relative frequencies of serious/not serious by sex
process_data.plot_serious_pivot(pivot_tb, 'route', ax2)
ax2.set_title('percentage serious vs not serious reports by sex');
ax2.set_xticklabels(['male','female']);
ax2.set_xlabel('');
ax2.set_ylabel('%');
```

We can see that there are significantly more reports of adverse reponses in male patients in the database. This might suggest that male patients are more likely to suffer adverse responses or that they are more likely to report adverse responses than female patients (or both).

One indication that suggests male patients might simply be more likely to report adverse effects (either directly or through a clinician) is that, of female reports, 55% of reports were for serious adverse effects compared to 45% for not serious. The ratio of serious and non-serious adverse reports for male patients in the data is 50:50.

We can calculate Pearson's χ^2 correlation coefficient to understand whether these results are significant (i.e. whether, for a given significance level, there is a correlation between sex and severity of response). We will choose a 99% significance level.

```
[13]: process_data.significance_test(pivot_tb[['not serious','serious']], 0.99)
```

```
dof = 1 probability = 0.990 | critical = 6.635 chi2 = 7.004
```

Reject null hypothesis. Variables dependent at the 99% confidence level.

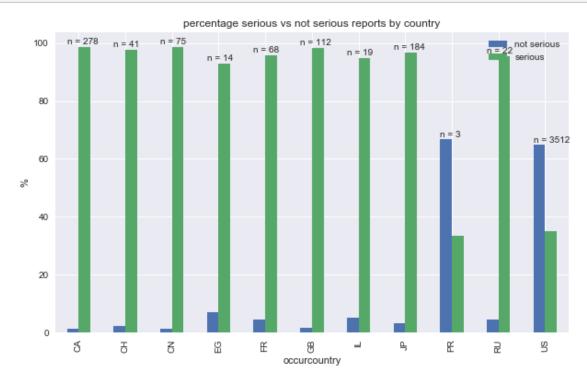

We find that there is sufficient evidence at the 99% significance level to reject the null hypothesis that there is no dependency between gender and the serious status of the report. There is a correlation between severity of the adverse response and sex. This feature may be useful in a predictive model.

1.2.5 Exploring the impact of country on adverse response outcomes

A similar analysis is performed on the country in which the adverse response took place.

```
[14]: # construct pivot table and plot
    pivot_tb = process_data.calculate_serious_pivot(pediatric_data, 'occurcountry')
    ax = process_data.plot_serious_pivot(pivot_tb, 'occurcountry', annotate=True)
    ax.set_title('percentage serious vs not serious reports by country');
    plt.show()

# calculate significance
    process_data.significance_test(pivot_tb[['not serious', 'serious']], 0.99)
```

```
dof = 10 probability = 0.990 | critical = 23.209 chi2 = 1038.201
```

Reject null hypothesis. Variables dependent at the 99% confidence level.

We find in this case also that, at the 99% significance level, there is sufficient evidence to reject the null hypothesis (i.e. that there is no correlation). This feature may be useful in a predictive model.

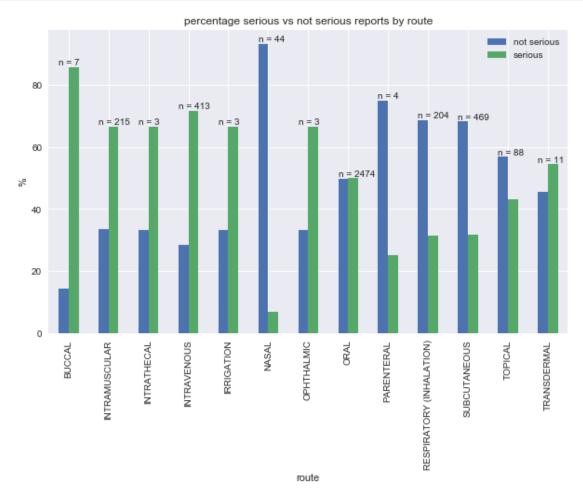

This is clear from examining the data by eye. However, we should be cautious that the 'not serious' cases are therefore nearly entirely coming from the US, which may introduce some bias in our analysis. Future analysis might rebalance the data to address this issue.

1.2.6 Exploring the impact of drug administration route on adverse response outcomes

We repeat the process again exploring the possibility that adverse response severity may be influenced by the administration route.

```
[15]: # calculate pivot table for severity against drug administration route
    pivot_tb = process_data.calculate_serious_pivot(pediatric_data, 'route')
    ax = process_data.plot_serious_pivot(pivot_tb, 'route', annotate=True)
    ax.set_title('percentage serious vs not serious reports by route');
    plt.show()

# calculate significance
    process_data.significance_test(pivot_tb[['not serious', 'serious']], 0.99)
```

dof = 12 probability = 0.990 | critical = 26.217 chi2 = 231.544

Reject null hypothesis. Variables dependent at the 99% confidence level.

We find that, again, there is enough evidence at a 99% significance level to reject the null hypothesis.

We have discovered at least three factors (sex, drug administration route and country) that are correlated with the severity of the adverse response reports. With further time, interpretation of these correlations would benefit from comparison to general population data, a larger dataset and a more detailed understanding of how and why adverse reports are made to the database.

1.3 Logistic regression model

I am interested to construct a model to predict the severity of adverse responses given certain information about a patient and the drug(s) that they are taking. The model would require significant fine tuning taking longer than the time available to complete this task. However, I include a representative approach using logistic regression to classify severity as serious or not serious. This simple model performs poorly but a variety of approaches might improve the accuracy of the model. I discuss these below.

```
[28]: from sklearn.impute import SimpleImputer
from sklearn.linear_model import LogisticRegression
from sklearn import metrics
from sklearn.model_selection import train_test_split
from sklearn.preprocessing import LabelEncoder
import process_data as process
```

I will establish a simple model based only on gender, age of patient and drug administration route. The data must first be cleaned further and preprocessed.

Further cleaning of the data

961 of 4991 rows with missing sex removed (19.25%)

Impute missing values and construct logistic regressor

```
[30]: # Select features to model
      X = data[['patient.patientsex', 'patient.patientonsetageyear', 'route_summary']]
      y = data['serious']
      # Split into training data and validation data (consider cross-validation later)
      X_train, X_valid, y_train, y_valid = train_test_split(X, y, test_size=0.3,__
      →random_state=0)
      # List categorical and numerical columns
      cols_cat = ['route_summary']
      patient_age = 'patient.patientonsetageyear'
      imputed_X_train = X_train.copy()
      imputed_X_valid = X_valid.copy()
      # Apply label encoder to each column with categorical data
      label_encoder = LabelEncoder()
      for col in cols_cat:
          imputed_X_train[col] = label_encoder.fit_transform(X_train[col].astype(str))
          imputed_X_valid[col] = label_encoder.transform(X_valid[col].astype(str))
      # Imputation: replace missing numerical data with mean value
      process.impute_on_mean(imputed_X_train, 'patient.patientonsetageyear')
      process.impute_on_mean(imputed_X_valid, 'patient.patientonsetageyear')
      # Imputation removed column names
      # Put them back
      imputed_X_train.columns = X_train.columns
      imputed_X_valid.columns = X_valid.columns
      # define logistic regression model
      log_reg = LogisticRegression();
      log_reg.fit(imputed_X_train, y_train);
```

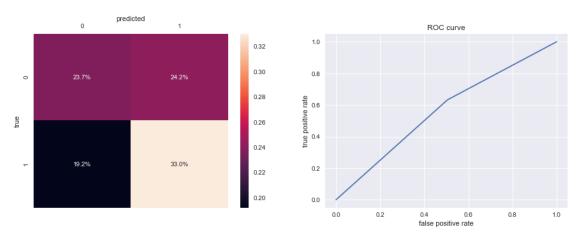

Determine accuracy of model

```
ax1.xaxis.tick_top()
ax1.xaxis.set_label_position('top');

# plot ROC curve
fpr, tpr, _ = metrics.roc_curve(y_valid, y_pred)
ax2.plot(fpr, tpr);
ax2.set_xlabel('false positive rate')
ax2.set_ylabel('true positive rate')
ax2.set_title('ROC curve')
plt.show()

print(metrics.classification_report(y_valid, y_pred))
```

Accuracy of logistic regression classifier on validation set: 0.57

	precision	recall	f1-score	support
0	0.55	0.49	0.52	578
1	0.58	0.63	0.60	631
accuracy			0.57	1209
macro avg	0.56	0.56	0.56	1209
weighted avg	0.57	0.57	0.56	1209

The accuracy is extremely poor for this model (little better than random). The ROC curve that plots false positive rate against true negative rate lies only slightly above the expected line for randomness. There are likely many reasons for this and I list possible next steps to improve the model below.

Next steps to improve the model

• Increase the volume of data

- Increase the number of features (e.g. country, drug type, pediatric indication, prescription/OTC)
- Balance the dataset
- Reintroduce less common administration routes
- Alter categorical data encoding (use one-hot encoding)
- Cross-validation
- Alternative approaches e.g random forest or XGBoost

Additionally, I would build the code into a pipeline rather than having each step as laid out above.

1.4 Conclusions

I have explored the FDA Adverse Reaction System and summaried the data it contains in the first notebook. Simple frequency plots and calculations are performed to understand where reports comes from, the number of reports over time, the gender breakdown of reports and the severity of the adverse responses reported.

In a second stage, I have pulled records directly from the data to create a dataset of 5,000 reports of adverse response in the patient age group category 'children'. Using these data, I have examined the correlation of severity of response with various other reported features including age, gender, drug administration route and country. In all cases except age, a statistically significant correlation is observed. The analysis could be improved by ensuring balanced samples and accounting for variations within the population at large. A larger dataset would also produce more reliable results. Given the age range found in the 'child' category, it would likely be sensible to include all pediatric patient age ranges in future studies.

In a final stage, I have constructed an illustrative logistic regression model to predict a response as 'serious' or 'not serious' as defined by the FDA. This model is overly simplistic and requires further refinement both for reliability and for accuracy.
